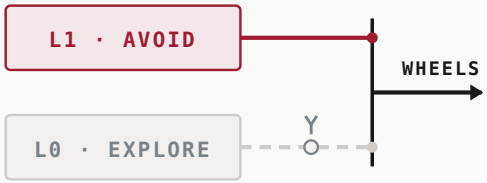
Two behaviors want the wheels. What decides?

Every architecture answers the same question — only the *rule* differs.

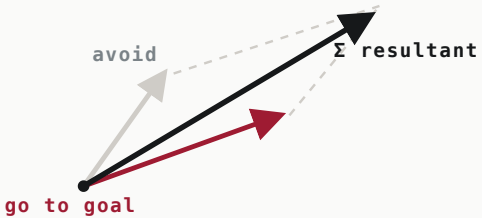
01 · SUBSUMPTION



Fixed priority

A higher layer suppresses a lower one. The winner is set *before* runtime; the loser is inhibited on the bus, not blended.

02 · MOTOR SCHEMAS



Vector sum

Both behaviors keep talking every tick. The wheels receive their sum, so conflict is averaged into one blended command.

03 · BEHAVIOR TREES

Explicit threshold

The rule lives in the tree as data — how many children must succeed. Arbitration becomes a value you can edit, not buried wiring.

THE POINT Arbitration *is* the parallelism story: wear it as **priority**, **summation**, or an explicit **policy** — and you have answered who gets the actuators.
